A 75 years old male was seen in our urologic office referring two episodes of left flank pain associated with nausea and vomiting. Physical examination was normal. Ultrasonography and intravenous pyelography showed a 2 cm lithiasis in left renal pelvis.

EWSL was performed over the pyelic lithiasis with complete fragmentation. Another intravenous pyelography was performed 6 months later which revealed a small lithiasis in left inferior calyx and a concentric ure-

teral stenosis in the ureteropelvic junction. Furthermore, numerous rounded formations along the ureter compatible with cystic ureteritis appeared.

Cystic ureteritis is a benign process consisting of suburothelial cysts that may be located in any part along the urothelium. It is associated with several types of infective and inflammatory processes that produce urothelium mucosa layer irritation, especially urinary tract infections and lithiasis.

Diagnosis is carried out by means of radiologic studies like intravenous pyelography and retrograde pyelogram which show specific findings.

No specific treatment is known, except the treatment of the concomitant pathology especially urinary tract infections and lithiasis.
